Abstract
We apply a quasi-model-independent strategy ("Sleuth") to search for new high $p_T$ physics in $\approx 100$ pb$^{-1}$ of $p\bar{p}$ collisions at $\sqrt{s} = 1.8$ TeV collected by the DØ experiment during 1992–1996 at the Fermilab Tevatron. We systematically analyze many exclusive final states and demonstrate sensitivity to a variety of models predicting new phenomena at the electroweak scale. No evidence of new high $p_T$ physics is observed.
It is generally recognized that the standard model, an extremely successful description of the fundamental particles and their interactions, must be incomplete. Unfortunately, the possibilities beyond the current paradigm are sufficiently broad that the first hint could appear in any of many different guises. This suggests the importance of performing searches that are as model-independent as possible. In this Letter we describe a search for new physics beyond the standard model, assuming nothing about the expected characteristics of the new processes other than that they will produce an excess of events at high transverse momentum ($p_T$). An explicit prescription (“Sleuth”) [1,2] is applied to many exclusive final states [1–3] in a data sample corresponding to approximately 100 pb$^{-1}$ of $p\bar{p}$ collisions collected by the DO detector [4] during 1992–1996 (Run I) at the Fermilab Tevatron.

The data are partitioned into exclusive final states using standard criteria that identify isolated and energetic electrons ($e$), muons ($\mu$), and photons ($\gamma$), as well as jets ($j$), missing transverse energy ($E_T$), and the presence of $W$ and $Z$ bosons [1]. For each exclusive final state, we consider a small set of variables given in Table I. The notation $\sum_{i=1}^n p_T^i$ is shorthand for $p_T^i$ if the final state contains only one jet, and $\sum_{i=1}^{n=3} p_T^i$ if the final state contains $n \geq 2$ jets, unless the final state contains only $n \geq 3$ jets and no other objects, in which case $\sum_{i=3} p_T^i$ is used. Leptons and $E_T$ from reconstructed $W$ or $Z$ bosons are not considered separately in the left-hand column. Because the muon momentum resolution in Run I was modest, we define $\sum p_T^j = \sum p_T^i$ for events with one or more electrons and one or more muons, and we determine $E_T$ from the transverse energy summed in the calorimeter, which includes the $p_T$ of electrons, but only a negligible fraction of the $p_T$ of muons. When there are exactly two objects in an event (e.g., one $Z$ boson and one jet), their $p_T$ values are expected to be nearly equal, and we therefore use the average $p_T$ of the two objects. When there is only one object in an event (e.g., a single $W$ boson), we use no variables, and simply count the number of such events.

**Table I.** A quasi-model-independently motivated list of interesting variables for any final state. The set of variables to consider for any exclusive channel is the union of the variables in the second column for each row that pertains to that final state.

The Sleuth algorithm requires as input a data sample, a set of events modeling each background process $i$, and the number of background events $b_i \pm \delta b_i$ from each background process expected in the data sample. From these we determine the region $R$ of greatest excess and quantify the degree $P$ to which that excess is interesting. The algorithm itself, applied to each individual final state, consists of seven steps:

1. We construct a mapping from the $d$-dimensional variable space defined by Table I into the $d$-dimensional unit box (i.e., $[0,1]^d$) that flattens the total background distribution. We use this to map the data into the unit box.

2. We define a “region” $R$ about a set of $N$ data points to be the volume within the unit box closer to one of the data points in the set than to any of the other data points in the sample. The arrangement of data points themselves thus determines the regions. A region containing $N$ data points is called an $N$-region.

3. Each region contains an expected number of background events $b_R$, numerically equal to the volume of the region times the total number of background events expected, and an associated systematic error $\delta b_R$, which varies within the unit box according to the systematic errors assigned to each contribution to the background estimate. We can therefore compute the probability $p_R^N$ that the background in the region fluctuates up to or beyond the observed number of events. This probability is the first measure of the degree of interest of a particular region.

4. The rigorous definition of regions reduces the number of candidate regions from infinity to $\approx 2^{N_dax}$. Imposing explicit criteria on the regions that the algorithm is allowed to consider further reduces the number of candidate regions. We apply geometric criteria that favor high values in at least one dimension of the unit box, and we limit the number of events in a region to fifty. The number of remaining candidate regions is still sufficiently large that an exhaustive search is impractical, and a heuristic is employed to search for regions of excess. In the course of this search, the $N$-region $R_N$ for which $p_R^N$ is minimum is determined for each $N$, and $P_N = \min_R (p_R^N)$ is noted.

5. In any reasonably-sized data set, there will always be regions in which the probability for $b_R$ to fluctuate up to or above the observed number of events is small. We determine the fraction $P_N$ of hypothetical similar experiments (hse’s) in which $p_N$ found for the hse is smaller than $p_N$ observed in the data by generating random events drawn from the background distribution and computing $p_N$ by following steps (1)–(4).

6. We define $P$ and $N_{\text{min}}$ by $P = P_{N_{\text{min}}} = \min_N (P_N)$, and identify $R = R_{N_{\text{min}}}$ as the most interesting region in this final state.

7. We use a second ensemble of hse’s to determine the fraction $P$ of hse’s in which $P$ found in the hse is smaller than $P$ observed in the data. The most important output of the algorithm is this single number $P$, which may loosely be said to be the “fraction of hypothetical similar experiments in which you would see an excess as interesting as what you actually saw in the data.” $P$ takes on values between zero and unity, with values close to zero indicating a possible hint of new physics. The computa-
The smallest $P$ found in the many different final states considered ($P_{\min}$) determines $P$, the “fraction of hypothetical similar experimental runs (hser’s) that would have produced an excess as interesting as actually observed in the data,” where an hser consists of one hse for each final state considered. $P$ is calculated by simulating an ensemble of hypothetical similar experimental runs, and noting the fraction of these hser’s in which the smallest $P$ found is smaller than the smallest $P$ observed in the data. Like $P$, $P$ takes on values between zero and unity, and the potential presence of new high $p_T$ physics would be indicated by finding $P$ to be small. The difference between $P$ and $P$ is that in computing $P$ we account for the many final states that have been considered. The correspondence between $P_{\min}$ and $P$ for the final states considered here is shown in Fig. 1(a).

$P$ is calculated by simulating an ensemble of hypothetical similar experimental runs, and noting the fraction of these hser’s in which the smallest $P$ found is smaller than the smallest $P$ observed in the data. Like $P$, $P$ takes on values between zero and unity, and the potential presence of new high $p_T$ physics would be indicated by finding $P$ to be small. The difference between $P$ and $P$ is that in computing $P$ we account for the many final states that have been considered. The correspondence between $P_{\min}$ and $P$ for the final states considered here is shown in Fig. 1(a).

DØ has previously analyzed several final states (2j, ee, $e\mu$, $W\gamma$, $WZ$, $Z\tau\tau$, and $Wj$) [5] in a manner similar to the strategy used here, but without the benefit of Sleuth. No evidence of physics beyond the standard model was observed. The final states we describe in this Letter divide naturally into four sets: those containing one electron and one muon ($e\mu$X); those containing a single lepton, missing transverse energy, and two or more jets ($W$+jets-like); those containing two same-flavor leptons and two or more jets ($Z$+jets-like); and those in which the sum of the number of electrons, muons, and photons is $\geq 3$ [3(e/$\mu$/γ)X].

The $e\mu$X data correspond to 108±6 pb$^{-1}$ of integrated luminosity. The data and basic selection criteria are identical to those used in the published $t\bar{t}$ cross section analysis for the dilepton channels [6], which include the selection of events containing one or more isolated electrons with $p_T^e > 15$ GeV, and one or more isolated muons with $p_T^\mu > 15$ GeV. In this Letter all electrons (and photons) have $|\eta_{\text{det}}| < 1.1$ or $1.5 < |\eta_{\text{det}}| < 2.5$, and muons have $|\eta_{\text{det}}| < 1.7$, unless otherwise indicated [7]. The dominant backgrounds to the $e\mu$X final states are from $Z/\gamma^* \rightarrow \tau\tau \rightarrow e\mu\nu\nu\nu$, and processes that generate a true muon and a jet that is misidentified as an electron. Smaller backgrounds include WW and $t\bar{t}$ production.

The $W$+jets-like final states include events in both the electron and muon channels. The $e\mu$X data [8], corresponding to 115±6 pb$^{-1}$ of collider data, have one electron with $p_T^e > 20$ GeV, $E_T > 30$ GeV, and two or more jets with $p_T^j > 20$ GeV and $|\eta_{\text{det}}| < 2.5$. The electron and missing transverse energy are combined into a $W$ boson if $30 < M_T^{e\mu} < 110$ GeV. The $e\mu$X final state data [9] correspond to 94±5 pb$^{-1}$ of integrated luminosity. Events in the final sample must contain one muon with $p_T^\mu > 25$ GeV and $|\eta_{\text{det}}| < 0.95$, two or more jets with $p_T^j > 15$ GeV and $|\eta_{\text{det}}| < 2.0$ and with the most energetic jet within $|\eta_{\text{det}}| < 1.5$, and $E_T > 30$ GeV. Because an energetic muon’s momentum is not well measured in the detector, we are unable to separate “$W$-like” events from “non-$W$-like” events using the transverse mass, as done above in the electron channel. The muon and missing transverse energy are therefore always combined into a $W$ boson. The $W\rightarrow \mu E_T$ final states are combined with the $W\rightarrow e E_T$ final states described above to form the $W$+jets final states. The dominant background to both the $e\mu E_T$ final states (and $\mu E_T$ final states) is from $W$+jets production. A few events from $t\bar{t}$ production and semileptonic decay are expected in the final states $W$3j and $W$4j.

The $Z$+jets-like final states also include events in both the electron and muon channels. The $ee$ final states [10] correspond to an integrated luminosity of 123±7 pb$^{-1}$. Offline event selection requires two electrons with transverse momenta $p_T^e > 20$ GeV and two or more jets with $p_T^j > 20$ GeV and $|\eta_{\text{det}}| < 2.5$. We use a likelihood method to help identify events with significant missing transverse energy [3]. An electron pair is combined into a $Z$ boson if $30 < M_{e\mu} < 100$ GeV, unless the event contains significant $E_T$ or a third charged lepton. The $\mu\mu$ final states [11] correspond to 94±5 pb$^{-1}$ of integrated luminosity. Events in the final sample contain two or more muons with $p_T^\mu > 20$ GeV and at least one muon with $|\eta_{\text{det}}| < 1.0$, and two or more jets with $p_T^j > 20$ GeV and $|\eta_{\text{det}}| < 2.5$. A $\mu\mu$ pair is combined into a $Z$ boson if the muon momenta can be varied within their resolutions such that $M_{\mu\mu} \approx M_Z$ and $E_T \approx 0$. The dominant background to both the $ee$ final states (and $\mu\mu$ final states) is from Drell-Yan production, with $Z/\gamma^* \rightarrow (e\mu/e\mu)$. Events in the $3(e/\mu/\gamma)X$ final states are analyzed using 123±7 pb$^{-1}$ of integrated luminosity. All objects (electrons, photons, muons, and jets) are required to be isolated, to have $p_T \geq 15$ GeV, and to be within the fiducial volume of the detector. Jets are required to have $|\eta| < 2.5$. $E_T$ is identified if its magnitude is larger than 15 GeV. The dominant backgrounds to many of these final states include $Z\gamma$ and $WZ$ production.

Refs. [1,3] provide examples of Sleuth’s performance on representative signatures. When ignorance of both WW and $t\bar{t}$ is feigned in the $e\mu$X final states, we find $P_{e\mu E_T} = 2.4\sigma$ and $P_{e\mu E_T}$ in DØ data, correctly indicating the presence of WW and $t\bar{t}$. When ignorance of both WW and $t\bar{t}$ is feigned in the $e\mu$X final states, we find $P_{e\mu E_T} = 1.9\sigma$. Excesses are observed with only 3.9 WW events expected in $e\mu E_T$ (with a background of 45.6 events), and only 1.8 $t\bar{t}$ events in $e\mu E_T$ (with a background of 3.4 events), even though Sleuth “knows” nothing about either WW or $t\bar{t}$. We are able to consistently find indications of the presence of WW and $t\bar{t}$ in an ensemble of mock experiments at a similar level of sensitivity.

In the W+jets-like final states we again feign ignorance of $t\bar{t}$ in the background estimate, and find $P_{\min} > 3\sigma$ in 30% of an ensemble of mock experimental runs on the final states $W$3j, $W$4j, $W$5j, and $W$6j. In the Z+jets-like final states we consider a hypothetical signal: a first generation scalar leptoquark with a mass of 170 GeV and a branching ratio into charged leptons of $\beta = 1$. In the
served. We find no evidence of new high signal more interesting than the most interesting candidate signal more interesting than the most interesting variables of the unit box. The circles are individual data events, and filled circles define the region selected by Sleuth. The regions chosen are seen to correspond to high $p_T$ in at least one dimension, as required by the imposed criteria. Visually, these regions do not appear to contain an unusual excess, and large $P$s are found. Similar results are obtained for other final states.

Table II summarizes the values of $P$ obtained for all populated final states analyzed in this article. Taking into account the many final states (both populated and unpopulated) that are considered, we find $P=0.89$, implying that 89% of an ensemble of hypothetical similar experimental runs would have produced a final state with a candidate signal more interesting than the most interesting observed in these data. Figure 1(b) shows a histogram of the $P$ values, in units of standard deviations, computed for the populated final states analyzed in this article, together with the distribution expected from a simulation of many mock experimental runs. Good agreement is observed. We find no evidence of new high $p_T$ physics in these data.
