ABSTRACT: A detailed study of the rescattering series is performed within a model, using a generalized procedure of eikonalization and fitted to the $pp$ and $\bar{p}p$ elastic scattering data. We estimate and compare the various rescattering corrections to be added to the Born contribution in the amplitude. We find that their number is finite, whereas it increases with the energy and the transfer, like does their importance. In the domain where data exist, we find also that a correct computation must include, at least, all two- and three-Reggeon exchanges and some four- and five-Reggeon exchanges. Any approximation aiming to reduce this (large) number of exchanges would be hazardous, especially when extrapolating. We extend our estimates in the domain of future experiments.

KEYWORDS: Phenomenological Models, Hadronic Colliders.
Contents

1. Introduction

The different aspects of Reggeon rescattering (or Regge cuts) have been investigated since the pioneering work of Gribov [1], who first developed a Regge calculus. A well defined procedure for determining individual diagrams corresponding to any multi-Reggeon exchanges has been developed in [2]. However these works and the following ones have been devoted mainly either to the study of analytical forms for the cuts or to the study of various summation schemes of multi-Reggeon diagrams [3]. Even when all the rescattering corrections were taken into account in the fits [4, 5] to experimental data, as a rule, determining the relative importance of various individual $n$-Reggeon exchange contributions has not received much interest (see however in [6] where this aspect is discussed).

Motivated by the experiments prospected [7] at RHIC and LHC, intended to measure the conventional observables in new ranges of energy and transfer, we are concerned by the following question. How should we take into account the rescattering corrections to the Born approximation in a correct computation of those observables?

To answer this question, one generally uses an eikonalization procedure which is also a remedy to cure the shortcoming of amplitudes violating the Froissart-Martin bound [8] at the Born level. However such a procedure is not unique and generally it involves a numerical integration in the Fourier-Bessel’s transform of the eikonalized amplitude over the impact-parameter (“$b$”). Furthermore the eikonalization, as a global process, hides the physical origin in terms of “Reggeon” exchanges.1

Our aim is to investigate numerically the rescattering corrections to the Born approximation: their relative importance, their physical meaning in terms of various Reggeon exchanges and their minimal number required by a correct reproduction of experimental data. For that purpose, we use a so-called generalized eikonalization (GE) procedure [9] recently applied to Regge models (e.g. [5]) and fitted to elastic $pp$ and $\bar{p}p$ scattering data.

---

1We affect the generic name “Reggeon” to any component of the elastic scattering amplitude we discuss for $pp$ and $\bar{p}p$ process, i.e. Pomeron and Odderon as well as $f$- and $\omega$-subleading trajectories.
In the amplitude describing the scattering process in the squared energy-transfer $(s, t)$ space, we can separate the Born contribution and the rescattering series

$$A_{pp}(s, t) = A_{pp, GE}(s, t) = a_{pp, \text{Born}}(s, t) + A_{pp, \text{rescat}}(s, t), \quad (1.1)$$

with

$$A_{pp, \text{rescat}}(s, t) = \sum_{n_+ = 0}^{\infty} \sum_{n_- = 0}^{\infty} a_{pp, n_+, n_-}(s, t). \quad (1.2)$$

Each term of this series (1.2) is analytically known for the models under interest. An example of driving the calculations is indicated in the appendix.\(^2\) We shall demonstrate that the series is conveniently approximated with a finite (although not small) number of terms. This possible truncation allows an easy study of the number and specificity of the exchanges that we must keep in the infinite summation to obtain a good accuracy in the final evaluation of the observables: the total cross-section, $\sigma_{\text{tot}}$, the ratio of the forward real to imaginary parts of the amplitude, $\rho$, the differential cross section, $d\sigma/dt$. Furthermore, with a suitably chosen Born amplitude, it avoids the time consuming numerical integration, generally required by any complete eikonalization procedure.

Each component of the series is labelled with two indexes $(n_\pm)$, each of them having a specific physical meaning. It is straightforward to constat that the first contribution to the rescattering series (1.2), with $(n_+, n_-) = (0, 0)$, is a sum of all diagrams of two-“Reggeon” exchanges. In fact, this $(0, 0)$ term involves ten exchanges so different as Pomeron-Pomeron, Pomeron-$f$, Pomeron-Odderon, Pomeron-$\omega$, $f-f$, $f$-Odderon, $f$-$\omega$, Odderon-Odderon, Odderon-$\omega$, $\omega-\omega$. It is easy to see that any term, with $n_+ + n_- = N$, is the sum of all diagrams with $N + 2$ Reggeons. We have no theoretical argument to sort out the magnitude of terms entering in (1.2), even when $N$ is as small as 1. When $N \gg 1$ many terms are included in the summation, with alternated signs inducing many cancellations. So, a careful numerical examination is necessary to find those exchanges which are the most important.

For the present estimation, we adopt the final amplitude of [5], which corresponds to a so-called “Dipole Pomeron” (DP) model\(^3\) with the GE method.

Such a choice has been made because it is a recently published amplitude respecting the Froissart-Martin bound, implying an involved formalism for the most general treatment up to now (to our knowledge) of the eikonalization process including 3 added free parameters. This complication may of course obscure the physical sense, but the fit is satisfying for the forward and non-forward data up to the largest

---

2 The calculation of the non-truncated series is performed as in [5] within the GE procedure [9].

3 Actually in this model the Pomeron “dipole”, linear combination of a simple and a double pole in the angular momentum $J$-plane, as explicated in [10], is complemented by 2 standard Reggeons, $f$ and $\omega$, by an Odderon dipole conveniently multiplied by an exponential damping factor.
explored $|t|$ (14 GeV$^2$ at the ISR, neighboring the Regge limit of application). It is, on our opinion, necessary to account data in the widest range of high energies and transfers to get confidence on predictive power outside the fitted sets of data (remember, the TOTEM project [7] plans measurements at the Large Hadron Collider up to at least $|t| = 10$ GeV$^2$ and it is precisely the LHC — or Tevatron, or RHIC — energy the most interesting to discuss at present).

The results we found (driven entirely by an analytical calculation) have not only an illustrative character, we have checked that our conclusions would be also valid for a “Monopole Pomeron” version, as used in [11], with this GE procedure.

2. Rescatterings and amplitude

To estimate the rescattering effects, in an absolute manner, we choose to plot the quantities (appearing basically as the most convenient)

$$\text{Re and Im} \left[ S_{n_+,n_-} \right], \quad S_{n_+,n_-} = a_{pp;\text{Born}}(s,t) + a_{pp;n_+,n_-}(s,t),$$

for $t = 0$ and for some representative $t$’s. We can easily compare the rescattering corrections with the results of the computations at the Born level and with the complete GE. We obtain, for the DP amplitude borrowed in [5], figures 1–6 yielding, on a linear scale, the imaginary (left) and real (right) parts of (2.1), labelled by $(n_+, n_-)$ and plotted versus the energy $\sqrt{s}$, (including the highest projected LHC energy) for six selected values of $t = 0., -0.5, -1., -2., -5., -10.$ GeV$^2$.

Alternatively, to estimate the rescattering effects relatively to the Born result, we may also rewrite the imaginary part of the $pp$ amplitude

$$\text{Im} (A_{pp}(s,t)) = \text{Im} (a_{pp;\text{Born}}(s,t)) \left( 1 + \sum_{n_+=0}^{\infty} \sum_{n_-=0}^{\infty} R_{n_+,n_-}^{(im)} \right),$$

and use this form to settle a hierarchy among the different terms. Explicitly,

$$R_{n_+,n_-}^{(im)} = \frac{\text{Im}(a_{pp;n_+,n_-}(s,t))}{\text{Im}(a_{pp;\text{Born}}(s,t))},$$

and similarly for the real part of the relative rescattering term, defining $R_{n_+,n_-}^{(re)}$.

We list in table 1 an example of these estimations, for the first values of the indexes $(n_+, n_-)$ (we limit somewhat arbitrarily $R^{(im)}$ and $R^{(re)}$ to one percent). The examination of the results, shown in figures 1–6 and table 1, calls for the following comments with increasing $|t|$:

---

4For commodity in the visualization on a linear scale, the amplitudes with their original normalization [5] have been divided here by $s$. 
Figure 1: Separate contributions of the main rescattering corrections (see the text) added to the Born result in the imaginary (left) and real (right) part of the $t = 0$ amplitude ($S_{n_+,n_-}(3)$, in dashed lines, labelled by $+ (n_+,n_-)$). Also shown in solid lines are the pure Born amplitude (Born) and the eikonalized amplitude, once the complete generalized eikonalization is performed (GEik).

Figure 2: Same as in figure 1 for $t = -0.5 \text{GeV}^2$

1. When $t = 0$ (see figure 1), adding separate corrections for $n_+ > 2, n_- > 0$ to the Born term gives curves that cannot be distinguished by eye from the Born one. In other terms, a good approximation of the rescattering series is achieved by keeping only the terms $(n_+,n_-) = (0,0), (1,0), (2,0)$. We can see that the rescattering corrections increase with the energy and we remark the change of sign and of scale shown by the real part, as required to account for the experimental characteristics of the $\rho$-ratio.

2. When $t$ is in the first diffraction cone (typically $t = -0.5 \text{GeV}^2$, see figure 2),
in addition to the three terms already listed for the forward amplitude, the terms with \((n_+, n_-) = (1, 1), (0, 1)\) bring small contributions to the amplitude which increase with the energy like the three other ones. Like in the forward case, the real and imaginary parts of the eikonalized amplitude are below the corresponding Born ones.

3. When \(t = -1 \text{ GeV}^2\) (see figure 3) in the vicinity of the dip seen in the \(pp\) angular distributions at the ISR, then, taken one by one, the corrections due to the rescattering still increase smoothly with the energy. But, and this is rather surprising, their sum tends towards a constant value, resulting in a GE limit almost parallel (and below) the Born estimation as soon as the energy exceeds 50 GeV.

4. The value \(t = -2 \text{ GeV}^2\) (see figure 4) is in a region where strong interferences
between the various terms exist; however, one remarks like for \( t = -1 \text{GeV}^2 \), an individual growth of the corrections with the energy and changes of sign resulting in a crossing of the Born and GE limit; otherwise stated, there is a clear global compensation of the corrections at the LHC energy for that transfer.

5. When \( t \) has an intermediate value, beyond the first dip-bump structure (\( t = -5 \text{GeV}^2 \), see figure 5), in addition to the five values of \((n_+, n_-)\) necessary to have a good precision when estimating the amplitude, one should also consider the term \((2, 1)\). In contrast with the preceding cases, (i) both imaginary and real part of the eikonalized amplitude are above the Born ones (ii) the growth with the energy of the absolute values of the corrections due to the rescattering which saturates at smaller \(|t|\) begins to decrease in the considered energy range.
Table 1: Typical contributions of the main rescattering terms specified by \((n_+ n_-)\) relative to the Born contributions (see the text). An arbitrary criterion of 1% has been set to limit their number. The energy and transfer are 1000 GeV, \(-0.5\) GeV\(^2\), respectively. Also quoted are the values of the amplitude computed at the Born level and once the complete generalized eikonalization is performed (GE).

(a reminiscence of the dip?). Finally, we remark that at the highest investigated energy, the eikonalized amplitude (real and imaginary part) is almost zero, but the corrections, though very small, may exceed the Born result by several orders of magnitude. They cannot be neglected since they bring the main contribution to the angular distributions.

6. When \(-t = 10\) GeV\(^2\) (see figure 6), highest value in the future prospects [7], the various corrections tend asymptotically to become very small at high energy (at the Tevatron and LHC) resulting in a numerical coincidence between the Born and the GE results corresponding to a very small differential cross-section. The same remarks as in the preceding case are valid.

In summary, it appears that the rescattering corrections to the amplitude cannot be neglected especially at high energy and transfer. In addition, the hierarchy of the corrections also depends (as expected) somewhat on the energy and transfer. As a general rule, for the Regge model considered here, one can only be sure that \((n_+, n_-) = (0,0)\) brings always the most important contribution and that limiting these indexes by \(n_+ = 2\) and \(n_- = 1\) is probably sufficient at not too high energy and transfer.
3. Discussion and conclusion

The total cross-section is directly related to the imaginary part of the forward amplitude, hence a part of the conclusions of the preceding section is fully usable. For the $\rho$-ratio, it is less evident to discuss the effects of the rescattering using the preceding considerations on the complex amplitude. The differential cross-section being proportional to the squared modulus of the amplitude, it is not straightforward to visualize the effects on its behavior when adding separately the rescatterings. Its non-linear character obscures the effects we want to investigate. The complete reconstruction of the amplitude requires the knowledge of both the imaginary and real part for all $(s,t)$ inside the experimental ranges (which is not possible from the data) and it is not quite evident that the conclusions of the preceding section on the complex amplitudes still hold for the real observables.

As in [5], when fitting the Dipole or the Monopole Pomeron model with the GE procedure, in the present work, many tests have proven than the $\chi^2$ strictly does not change if we overpass $n_+ = 2$ and $n_+ = 1$, keeping more than $3 \times 2 = 6$ terms in the series (1.2) (i.e. $(n_-+n_-) = (0,0), (1,0), (2,0), (0,1), (1,1), (2,1)$). Further, a poor approximation is realized with two $(0,0)$ and $(1,0)$, or better with three of them $(0,0), (1,0), (2,0)$. That does NOT mean that, if we scrutinize in particular some differential cross-sections at intermediate $|t|$-values and at high energy, one knows...
Figure 8: Modifications of a part of the fit in [5] and of prediction at RHIC energy (solid line) when the rescattering series is approximated with the two-Reggeon exchanges alone (dotted line), i.e. \((n_+, n_-) = (0, 0)\), or when the three-Reggeon exchanges are added, i.e. \((n_+, n_-) = (0, 0)\), (10), (01) (dashed line).

which kind of approximation is to be used, because (i) the involved data are scarce and then they are depreciated in the global minimization procedure (ii) the addition of higher terms required in the amplitude may have significant consequences on the angular distribution for some \((s, t)\), meriting a separate study.

The last, but not the least important item we discuss is the use of various approximations.

A mean to see in which kinematical range an approximation is efficient is to examine numerically its consequences on the agreement with fitted observables or, outside the experimentally investigated domain, with the predictions of non-truncated series (GE case), which reproduces the data. We choose the \(pp\) angular distributions, known at the ISR up to rather large transfers, and extrapolate up to future experimental conditions. We comment our results on the following points.

- Assuming only two-Pomeron exchange as a first approximation is a pioneering idea to create the dip [12] and we know in advance it should be insufficient. In our language, one extract the Pomeron-Pomeron contribution from the ten possible two-Reggeon exchanges with \((n_+, n_-) = (0, 0)\). Figure 7 is an illustrative example of the inadequacy of this double approximation, for the differential cross-section, as soon as the transfer is not equal zero.
Table 2: Upper indexes of the rescattering series \((N_+, N_-)\), necessary to approximate, within a precision of 1%, the GE value of the \(pp\) differential cross-section (from the limit of non-truncated series), extrapolated for the energy and transfer of the future experiments [7].

- The next step we consider, is to keep all the ten two-Reggeon exchanges, i.e. when approximating the series (1.2) with its first term, \((n_+, n_-) = (0, 0)\). The result is shown in figures 7 and 8. The agreement with the non-truncated series is far from being good. We note a slight improvement with respect to the two-Pomeron approximation, especially in reproducing a larger part of the first cone, in creating a dip (although too high, but unfortunately a second dip is also created) and in reducing the differential cross-section at high \(|t|\) (which remains still too high).

- We go on further by taking into account in addition all the three-Reggeon exchanges, i.e. limiting the series to the first three terms \((n_+, n_-) = (0, 0)\) (two-Reggeon exchanges) and \((n_+, n_-) = (0, 1), (1, 0)\) (three-Reggeon exchanges). The agreement is better than in the preceding approximation (see figure 8) but is still unsatisfying. Here we can only say that all the three-Reggeon exchanges contribute significantly to improve the agreement with the known data and, when these are lacking, to get near the GE results.

- We are in perfect agreement with the statements of the preceding section concerning the number and specificity of exchanges that must be retained to approximate the series with its limit, given here by the generalized eikonalization procedure. From extrapolated differential cross-section calculations, we find that the upper bound of the index \(n_+\) (let us call it \(N_+\)) and, to a lesser extend \(N_-\), upper bound of \(n_-\), leading to a convergence towards the GE cross-section, increases with \(s\) and mostly with \(t\) as indicated in table 2, giving rise to a very complex picture of rescatterings in terms of possible diagrams. Whether or not this turns out to be true, only new data can decide of the quality of the extrapolation and its consequences.
Turning to an other type of approximation, we mention, as a widespread opinion, that one can neglect the $f$- and the $\omega$- contributions (and consequently, their rescattering terms) at high energy. We have tested this assertion (giving a sense to the adjective “high”), and found that the $\omega$-Reggeon (with all its rescatterings) is fully negligible only if $\sqrt{s} \gtrsim 500\text{ GeV}$, while for the $f$-Reggeon, the same is true only at an energy higher than a few TeV.

Clearly, limiting the rescatterings to the three- or two-Reggeon exchanges (and a fortiori to the two-Pomeron exchanges) gives a very crude (wrong) estimation of the angular distribution as soon as $-t$ exceeds zero. A correct picture of the rescatterings, compatible with presently available data, requires to limit the series to at least $(N_+, N_-) = (2, 1)$. Indeed, these six couples of indexes correspond to a quite large number of exchanges (ten for the $(0,0)$ two-Reggeon exchanges, twenty for the $(0,1),(1,0)$ three-Reggeon exchanges, etc. but we remark that the complete list of the all four- and five-Reggeon exchanges is not required).

Finally it is worth pointing out that the substance of the present paper would have been unchanged if we have illustrated it with the GE Monopole Pomeron model instead of the GE Dipole Pomeron model.

Acknowledgments

We thank L. Jenkovszky for a critical discussion.

A. Born amplitude and Dipole model

Selecting and completing the information given in [5, 9], we collect here the useful formula to understand and perform the rescattering calculations in the “Generalized Eikonalization” (GE) procedure for the “Dipole Pomeron” (DP) model. We emphasize that all the relevant expressions are analytical (they do not require any numerical integration).

A.1 Input Born in the $s,t$ space. The Dipole Pomeron model

We focus on the (dimensionless) Born crossing-even and -odd amplitudes $a_\pm(s,t)$ of the $pp$ and $\bar{p}p$ reactions\footnote{Once again, $+(-)$ correspond to $\bar{p}p$ ($pp$) process; note that the normalization of [5] is used and that the coupling constants $a_P, a_O, a_f, a_\omega$ are reals.}

$$a_{pp;\text{Born}}^p(s,t) = a_+(s,t) \pm a_-(s,t), \quad (A.1)$$

starting point to get the eikonalized amplitudes $A(s,t) = A_{pp}^p(s,t)$ used to fit:
(i) the total cross-sections
\[ \sigma_{\text{tot}} = \frac{4\pi}{s} \Im A(s, t = 0), \]  
(A.2)

(ii) the differential cross-sections
\[ \frac{d\sigma}{dt} = \frac{\pi}{s^2} |A(s, t)|^2, \]  
(A.3)

(iii) and the ratios of the real to the imaginary forward amplitudes
\[ \rho = \frac{\Re A(s, t = 0)}{\Im A(s, t = 0)}. \]  
(A.4)

The crossing even part in the Born amplitude is a Pomeron, to which a \( f \)-Reggeon is added, while the crossing odd part is an Odderon (plus an \( \omega \)-Reggeon)
\[ a_+(s, t) = a_P(s, t) + a_f(s, t), \quad a_-(s, t) = a_O(s, t) + a_\omega(s, t). \]  
(A.5)

For simplicity, in our DP model, the two Reggeons have been taken in the standard form
\[ a_R(s, t) = a_R \tilde{\eta}_R s^{\alpha_R(t)} e^{b_R t}, \quad (R = f \text{ and } \omega), \quad \eta_f = 1, \quad \eta_\omega = i, \]  
(A.6)

with linear trajectories
\[ \alpha_R(t) = \alpha_R(0) + \alpha_R' t, \quad (R = f \text{ and } \omega). \]  
(A.7)

Here a “dipole” is chosen for the Pomeron (i.e. a linear combination of a simple pole with a double pole)
\[ a_P(s, t) = a_P^{(D)}(s, t) = a_P \tilde{s}^{\alpha_P(t)} [e^{b_P(\alpha_P(t)-1)}(b_P + \ell n \tilde{s}) + d_P \ell n \tilde{s}]. \]  
(A.8)

The Odderon is obtained with the same requirements as for the Pomeron, but multiplied by a convenient damping factor killing it at \( t = 0 \) in order to respect the common knowledge
\[ a_O(s, t) = (1 - \exp \gamma t) i a_O^{(D)}(s, t); \]  
(A.9)

i.e. the amplitude on the r.h.s. \( a_O^{(D)}(s, t) \) is constructed along the same lines as \( a_P^{(D)}(s, t) \), changing only the parameters. As usual,
\[ \tilde{s} = \frac{s}{s_0} e^{-i\pi/2}, \quad (s_0 = 1 \text{ GeV}^2), \]  
(A.10)

enforces \( s - u \) crossing and \( \alpha_i(t) \) are the trajectories taken, for simplicity, of the linear form
\[ \alpha_i(t) = 1 + \delta_i + \alpha_i' t, \quad (i = P, O), \]  
(A.11)

and verifying the unitarity constraints
\[ \delta_P \geq \delta_O, \quad \text{and} \quad \alpha_P' \geq \alpha_O'. \]  
(A.12)
A.2 Born amplitude in the \( s, b \) space

In eikonal models, the scattering amplitudes are expressed in the impact-parameter ("b") representation \((s,b)\) space. First, one defines the Fourier-Bessel’s (F-B) transform of the Born amplitude

\[
h_{pp}(s,b) = \frac{1}{2s} \int_0^\infty d^2p_{pp,Born}(s,-q^2) J_0(bq) dq , \quad \text{with} \quad q = \sqrt{-t} . \tag{A.13}
\]

This is related to the eikonal function ("eikonal" for brevity) by

\[
\chi_{pp}(s,b) = 2 h_{pp}(s,b) . \tag{A.14}
\]

In all eikonalization procedures, one first derives the eikonalized amplitude in the \( b \)-representation \( H_{pp}(s,b) \); the inverse F-B transform leads then to the usual eikonalized amplitude in the \( s,t \) space

\[
A_{pp}(s,t) = 2s \int_0^\infty H_{pp}(s,b) J_0(b\sqrt{-t}) db . \tag{A.15}
\]

The main technical problem of eikonalization is the derivation of \( H_{pp}(s,b) \) once \( h_{pp}(s,b) \) are given (for details, see [9]).

Although not required in practice since it is integrated when eikonalizing, and consequently it is an intermediate quantity, we give here the expression of the Born amplitude in the impact parameter representation (half of the eikonal function)

\[
h_{pp}(s,b) = \frac{1}{2} \chi_{pp}(s,b) = h_f(s,b) + h_P(s,b) \pm [h_O(s,b) + h_\omega(s,b)] , \tag{A.16}
\]

with the DP model, defined above.

For the secondary Reggeons, we obtain

\[
h_{R}(s,b) = \frac{1}{2} \eta_R a_R \tilde{s}^{\alpha_R(0)} \left( \frac{\exp(-b^2/4B_R)}{2B_R} \right) = \frac{1}{2} \chi_{R}(s,b) , \tag{A.17}
\]

with (see also (A.6) and (A.7))

\[
B_R \equiv B_R(s) = \alpha_R' \ln s + b_R , \quad R = (f, \omega) , \quad \eta_f = 1 , \quad \eta_\omega = i . \tag{A.18}
\]

The Pomeron dipole splits into 2 components

\[
h_P(s,b) = \frac{-i}{4\alpha'_P s_0} \left( e^{r_1_P b_P - \frac{b^2}{2r_1_P s}} + d_P e^{r_2_P b_P - \frac{b^2}{2r_2_P s}} \right)
\]

\[
\equiv \frac{1}{2} \chi_P(s,b) = \frac{1}{2} \left( \chi_{P1}(s,b) + \chi_{P2}(s,b) \right) . \tag{A.19}
\]
The Odderon dipole with its damping factor yields

\[
    h_O(s,b) = \frac{a_O}{4\alpha'_O s_0} \left( e^{r_{1,0} \delta_O - \frac{\delta^2}{4m^2_{1,0}}} + d_O e^{r_{2,0} \delta_O - \frac{\delta^2}{4m^2_{2,0}}} \right) - \\
    \frac{a'_O}{4\alpha'_O s_0} \left( e^{r_{1,0} \delta_O - \frac{\delta^2}{4m^2_{1,0}}} B_1 O + d_O e^{r_{2,0} \delta_O - \frac{\delta^2}{4m^2_{2,0}}} B_2 O \right)
\]

\[
    \equiv \frac{1}{2} \chi_O(s,b) = \frac{1}{2} \left( \chi_{O1}(s,b) + \chi_{O2}(s,b) + \tilde{\chi}_{O1}(s,b) + \tilde{\chi}_{O}(s,b) \right). \tag{A.20}
\]

We have defined (see also (A.8)–(A.11))

\[
    r_{1,J} \equiv r_{1,J}(s) = \ell n s + b_J, \quad r_{2,J} \equiv r_{2,J}(s) = \ell n s, \quad (J = P,O), \tag{A.21}
\]

and

\[
    B_{i,P} \equiv B_{i,P}(s) = \alpha'_P r_{i,P}, \quad B_{i,O} \equiv B_{i,O}(s) = \alpha'_O r_{i,O}, \\
    \tilde{B}_{i,O} \equiv \tilde{B}_{i,O}(s) = \alpha'_O r_{i,O} + \gamma, \quad (i = 1,2). \tag{A.22}
\]

### A.3 Rescattering series

We rewrite the rescattering series (1.2) (part of the eikonalized amplitude added to the Born contribution (1.1))

\[
    A_{pp,\text{rescat}}^{\bar{p}p}(s,t) = \sum_{n_+ = 0}^{\infty} \sum_{n_- = 0}^{\infty} a_{pp,n_+,n_-}^{\bar{p}p}(s,t), \tag{A.23}
\]

with the \((n_+, n_-)\) term in the general case of three parameters \((\lambda_+, \lambda_0)\) of the GE procedure

\[
    a_{pp,n_+,n_-}^{\bar{p}p}(s,t) = i \s e \frac{(i\lambda_+)^{n_+} (\pm i\lambda_-)^{n_-}}{(n_+ + n_- + 2)!} \times \\
    \times \left( F_{n_+,n_-}(z) \cdot I + F_{n_-n_+}(z) \cdot II + G_{n_+,n_-}(z) \cdot III \right), \tag{A.24}
\]

where the hypergeometric function \(2F_1\) has been introduced in \(F\) and \(G\), functions of the argument

\[
    \lambda^2 = \frac{\lambda_+ \lambda_-}{\lambda_+ + \lambda_-}
\]

\[
    F_{n_+,n_-}(z) = z(n_+ + 1) \cdot 2 \text{F}_1(1 - n_+, -n_+ + 2; z) \cdot (1 - \delta_{n_+,0}) + \delta_{n_+,0}, \\
    G_{n_+,n_-}(z) = 2 \text{F}_1(-n_-, -n_+ + 1; z). \tag{A.25}
\]

The inverse Fourier-Bessel transforms are the following three functions in the \(s, t\)
where

\[ I = \lambda_+ \sum_{\ell=0}^{n_+} \sum_{m=0}^{n_-} \binom{n_+ + 2}{\ell} \binom{n_-}{m} \cdot \text{Int}_{n_+, 2-\ell, n_- - m, \ell, m}(s, t), \]

\[ II = \lambda_- \sum_{\ell=0}^{n_+} \sum_{m=0}^{n_-} \binom{n_+ + 2}{\ell} \binom{n_- + 2}{m} \cdot \text{Int}_{n_+, \ell, n_- + 2, \ell, m}(s, t), \]

\[ III = \pm 2 \frac{\lambda_+ \lambda_-}{\lambda_0} \sum_{\ell=0}^{n_+ + 1} \sum_{m=0}^{n_- + 1} \binom{n_+ + 1}{\ell} \binom{n_- + 1}{m} \cdot \text{Int}_{n_+, 1-\ell, n_- + 1 - m, \ell, m}(s, t). \tag{A.26} \]

\( \binom{n}{k} \) is the binomial coefficient and \( \text{Int}(s, t) \) is the integral over the four eikonals defined above, i.e.

\[ \text{Int}_{\lambda, \mu, \ell, m}(s, t) = \int_0^\infty \chi_{\ell}^\lambda(s, b) \chi_{\ell}^\mu(s, b) \chi_{\ell}^\nu(s, b) J_0(b\sqrt{-t}) b db. \tag{A.27} \]

When the dipole Odderon does contain a damping factor at \( t = 0 \), this integral writes

\[ \text{Int}_{\lambda, \mu, \ell, m}(s, t) = C \sum_{\lambda'=0}^{\lambda} \sum_{\mu'=0}^{\mu-\sigma} \sum_{\sigma=0}^{\sigma} \lambda' (\mu') (\sigma) (\sigma) \times \]

\[ \times \exp \left[ r_{1, \ell} \delta_P (\lambda - \lambda') + r_{2, \ell} \delta_P \lambda' + \right. \]

\[ + r_{1, 0} \delta_O (\mu - \mu') + r_{2, 0} \delta_O (\mu' + \nu) \times \]

\[ \times d_{\ell}^{\lambda'} d_{\ell}^{\mu' + \nu} \left( - \frac{B_{1,0}}{B_{1,0}} \right)^{\sigma-\nu} \left( - \frac{B_{2,0}}{B_{2,0}} \right)^{\nu} \cdot \text{int}(s, t), \tag{A.28} \]

where

\[ C \equiv C(s) = \left( \frac{-ia_P}{2\alpha' P s_0} \right)^{\lambda} \left( \frac{a_O}{2\alpha' O s_0} \right)^{\mu} \left( \frac{a_f \tilde{\alpha}_f^{(0)}}{2 B_f s} \right)^{\ell} \left( \frac{i \tilde{a}_w \tilde{\alpha}_w^{(0)}}{2 B_w s} \right)^m; \]

\[ \text{int}(s, t) = \int_0^\infty \exp \left( -\frac{D b^2}{4} \right) J_0(b\sqrt{-t}) b db = \frac{2}{D} \exp \left( \frac{t}{D} \right); \]

\[ D \equiv D(s) = \frac{\lambda - \lambda'}{B_{1, P}} + \frac{\lambda'}{B_{2, P}} + \frac{\mu - \sigma - \mu'}{B_{1, O}} + \frac{\mu'}{B_{2, O}} + \frac{\sigma - \nu}{B_{1, O}} + \frac{\nu}{B_{2, O}} + \frac{\ell}{B_f} + \frac{m}{B_w}. \tag{A.29} \]
