BEAM DIAGNOSTICS FOR SPIRAL2 RNB FACILITY

Abstract

The SPIRAL2 project is based on a multi-beam driver facility in order to allow both ISOL and low-energy in-flight techniques to produce intense radioactive ion beams (RIB) in a new Facility. A superconducting linac capable of accelerating 5-mA deuterons up to 40 MeV is used to bombard both thick and thin targets. These primary beams will be used for the RIB production by several reaction mechanisms (fusion, fission, etc.) The production of high intensity RIB will be based on fission of uranium target induced by neutrons.

These exotic particles will be produced, ionized, selected in a dedicated production building and transported to the existing CIME cyclotron for post acceleration. After this, they will be used in the present experimental area of GANIL. The construction phase of SPIRAL2 was officially started in 2005.

The beam diagnostics for the production facility allow a pre-tuning with a stable beam followed by an extrapolation to the radioactive beam. Some diagnostic devices may also provide for equipment protections and for the safety systems.

An overview is presented of the diagnostics which will allow tuning and control of the RIB in this new production facility.

SPIRAL2 RNB FACILITY

The RNB facility will produce, from a high intensity primary beam, radioactive ion beam in a red radiological cave. The production of high intensity RIB will be based on fission of uranium target induced by neutrons. The mono-charged secondary beams will be selected in the 1+ beam line, used for low energy experiment or multi ionized to be post accelerated in the existing Ganil.

TUNING AND CONTROL METHODS

The tuning principle of the SPIRAL2 beams consists of pre-tuning with a stable beam followed by an extrapolation to the radioactive beam.

PRELIMINARY TUNING IN STABLE BEAM

Beam Intensity Measurement

Measurement of the beam intensity in the lines is based on the use of Faraday cups (Fig. 3) and a linear current to voltage converter. Their measurement dynamics extends from $10^9$ pps up to $I_{\text{max}}$ ($P<50W$) with an absolute accuracy of a few percent.

Beam Profile and Position Measurement

The measurement of the beam transverse profile in the lines is carried out by secondary emission multiwire profilers (Fig. 4). The principle is based on electron emission under the impact of the beam on wires. The range measurement is $10^9$ pps – $10^{13}$ pps for energy from some keV to 25 MeV/A and the absolute positional accuracy is better than 1 mm.

It gives transverse profile dimensions and the gravity centre of the beam along a horizontal and vertical axis. This information will be distributed via electronic processing according to Ethernet or MODBUS protocol with the Spiral2 Command-Control.
For Spiral2 facilities, electronics components will be far away from the sensor to be protected from the radiation. Studies will therefore have to be conducted on a new electronic device with a length of approximately 20 m of cables (Fig. 5).

**Beam Radiation Measurement.** In the case of “routine intensity measurement” in beam lines, it will be possible to use devices containing implantation foil and semiconductors to measure the beam radioactivity (gamma radiation) and control the transmission in the beam line.

These interesting devices are under development at Ganil (resolution: 0.8 % FWHM at 662 keV).

**Beam Profile Measurement**

**Secondary Emission Foil Profiler.** Profilers with emissive foil and micro-channel plates will also allow measurement of the transverse profile after CIME, with no lower energy limit. This is a low intensity beam profile monitor. The principle is a collection of the secondary electrons in a drift space which are amplified with an MCP stage and collected on an x-y grid for a required resolution of 1 mm. They are currently under development at GANIL (Fig. 8).

**Very Low Intensity and Low Energy Profiler.** To control the radioactive beam in the low energy line of Spiral2, beam localisation and beam quantification should be carried out. When there is no stable beam pollution, beam detection with electric charge measurement is possible. One solution with weak beam energy would consist in direct interaction of the beam with a micro-

---

**RADIOACTIVE ION BEAM TUNING**

**Low Beam Intensity Measurement**

**Electrical Measurement.** The intensity measurement will have to be carried out using a Faraday cup with logarithmic current/voltage converter, like that used on the SPIRAL1 facility. Their measurement dynamics extend from some \(10^7\) to \(10^{14}\) pps. This Faraday cup has electric shielding to measure weak beam intensity over a large dynamic range.
channel plate without emissive foil. This development will start in 2010.

**Secondary Emission Multiwire Profiler with Gas Circulation for Post Accelerated Beam.** Transverse beam profile measurement in the lines after existing CIME cyclotron will be carried out, in most cases, by profilers with gas circulation. The principle is like a gas ionisation chamber. The low limit for this profiler is due to the thickness of the input window. This sensor is under development and the results are very good: Resolution better than 1 mm for $10^2$ to $10^4$ pps with a gas pressure of 10 mbar of C4H10 or C3F8 and with an input window thickness of 6 μm of Mylar.

**Faraday Cup Associated With a Fast Electrostatic Deflector**

In order to provide users with a beam which is as continuous as possible, a device equipped with an electrostatic deflector in front of a low intensity Faraday cup which integrates the average intensity could be installed. This electrostatic deflector could deflect, for example, at a frequency of 1 kHz, with a useful ratio for measurement of 5%, leaving 95% of the continuous beam for the users (Fig. 11).

![Figure 11: Faraday cup associated with a fast electrostatic deflector.](image)

In this case, a Faraday cup resolution of 2 pAe, by guaranteeing the “deflector” function, provides an indirect resolution of 36 pAe on the beam users. This device could control and guaranty in all circumstances a user beam threshold of about 360 pAe ($2 \times 10^9$ pps). It is sufficient.

**CONCLUSION**

The feedback of the Ganil and Spiral1 operation is a major factor contributing to optimum design of the Spiral2 facility and definition of the beam tuning methods. The beam diagnostic definition benefits from this feedback. Some Spiral1 diagnostics will be reused; others are in development.

However all diagnostics will have to answer:
- new and strong nuclear environment requirements (remote handling, simplicity, robustness, reliability),
- requirement for behaviour at high vacuum (low degassing rate at a pressure of $10^{-8}$ mbar in order to limit the beam losses in the n+ line).
