HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L'archive ouverte pluridisciplinaire **HAL**, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d'enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.

First evidence of hard scattering processes in single tagged $\gamma\gamma$ collisions

DELPHI Collaboration

Abstract

For the first time, multihadronic production from single tagged $\gamma\gamma$ collisions has been studied, where one of the scattered leptons was tagged at very low virtual photon absolute mass squared ($\langle Q^2 \rangle = 0.06 \text{ (GeV}/c^2)^2$). Data collected during 1991 and 1992 in the DELPHI experiment at LEP are shown to agree well with predictions which included the non-perturbative vector meson dominance model in which the interacting photons are assumed to have converted into a vector meson (ρ , ω or ϕ), a quark-parton model which describes direct photon interactions and a QCD-based model which considers the photon to have quark and gluon structure functions. Five different parametrizations of these structure functions were used and the predictions compared with the data. This study confirms recent results from no-tag experiments in requiring a QCD-based component to successfully describe the data, indicating that the photon has a significant partonic content.

1 Introduction

Two-photon scattering in e^+e^- storage rings has been studied in many experiments at PEP [1], PETRA [2], and recently at KEK [3] and LEP [4–7]. The production of multihadronic final states, X , in the reaction $e^+e^- \rightarrow e^+e^-X$ is possible due to collisions of the clouds of virtual photons radiated by high energy electrons and positrons. If both the electron and positron in the final state go down the beam pipe and remain undetected, (the no-tag or untagged mode), only the multihadronic system can be studied. In the single-tagged case one of the outgoing scattered leptons is measured while double-tagged events have both measured. The detected lepton provides additional information about the event kinematics, allowing more detailed studies of such events to be made than is possible with untagged events. Other features of the tagging are useful : the data sample is free from Z^0 contamination and it becomes possible to study and reject most of the LEP machine background. Unfortunately, as the scattered leptons emerge preferentially along the beam direction, requiring that one or both leptons be scattered at a large enough angle to be detected results in a large suppression of the $\gamma\gamma$ cross-section compared with the untagged case. A review of two-photon physics may be found in ref. [8] and recent reports of work in this field may be found in ref. [9]. Interesting results were reported there by the AMY Collaboration [10] for no-tag experimental conditions giving the first satisfactory qualitative description of data by including QCD-based calculations of the hard scattering of hadronic constituents of the photon.

Here, first evidence of hard scattering subprocesses in single tagged $\gamma\gamma$ events is reported and a comparison is made between the data and five different parton density parametrizations used to describe those subprocesses. Data taken with the DELPHI detector during 1991 and 1992, corresponding to an integrated luminosity of 28.4 pb^{-1} , were used to analyze the hadronic final states produced in single tagged $\gamma\gamma$ collisions at a mean value of the tagged-photon absolute squared-mass, Q^2 , around $0.06 \text{ (GeV}/c^2)^2$.

The paper is organized in the following way. Section 2 gives a brief overview of the theory of $\gamma\gamma$ interactions, with emphasis on the three models used for describing the data. Then the implementation of the $\gamma\gamma$ theory in simulation is described. The DELPHI detector components and the methods used for $\gamma\gamma$ event selection are described briefly in Section 3. The detector for luminosity measurement, the Very Small Angle Tagger (VSAT), used here to tag the scattered leptons, is described in more detail. Section 4 deals with the rejection of background to the $\gamma\gamma$ events and the results are discussed in Section 5.

2 Theoretical framework and simulation

The overall kinematics of a single tagged $\gamma\gamma$ reaction is represented in Figure 1a. The four-momentum transfer $Q^2 = -q_1^2$ is defined as the absolute value of the squared mass of the virtual photon radiated from the tagged electron or positron. In the high Q^2 region the $e\gamma$ Deep Inelastic Scattering (DIS) formalism applies with a quasi-real photon as the target, coupling to quarks in a point-like fashion or through a vector-meson bound-state (see for example [4]). At moderate x ($x = Q^2/(Q^2 + W^2)$) where W is the invariant mass of the produced hadronic system) the data from previous e^+e^- collider experiments are in qualitative agreement with a composite model combining the Vector-meson Dominance Model (VDM) and the Quark-Parton Model (QPM), illustrated in Figures 1b and 1c. The photon structure function is then extracted from the data using unfolding methods [6]. The theoretical description of the low- x region is still not fully satisfactory. An excess of

events over the incoherent sum of the expectations from the VDM and QPM was observed experimentally [1–3]. It was also observed that a significant fraction of those events did not have the simple two-jet topology expected from the model. QCD-based calculations of non-diffractive hard-scattering of hadronic constituents of the photons have shown that high transverse momentum hadrons could be produced in multi-jet configurations [11,12]. In this low- x region, jets are produced with high transverse momentum (p_T) with respect to the $\gamma\gamma$ axis (which is usually very close to the beam axis for the single tag case) which implies high $\gamma\gamma$ invariant masses W .

Going to low Q^2 , jet production with $(p_T/c)^2$ greater than Q^2 is expected to be more frequent. In the Leading Log approximation of QCD, the hard scattering subprocesses shown in Figures 1d and 1e start to grow, even to dominate when going to very low Q^2 . In these subprocesses, called sometimes QCD Resolved Photon Contribution (hereafter denoted QCD-RPC), some partons within the photons can interact with each other. Therefore, a density function formalism is appropriate to express the chance of finding a parton in the photon with given momentum fraction. These QCD-RPC subprocesses offer the possibility of experimentally measuring the quark and gluon densities of the photon [3,4] and hence testing the theoretical models. The hard scattering subprocesses shown in Figures 1d and 1e require high four-momentum transfers (or high p_T^2) of partons to probe the structure of one or both photons and to resolve them into their partonic constituents.

Thus the scheme used to describe the $\gamma\gamma$ process can be represented as follows. The fully non-perturbative contribution is described through VDM as the diffractive scattering of vector mesons with the cross-section given by Rosner [13]

$$\sigma_{\gamma\gamma}(W^2, Q^2, P^2) = F_{VDM}(Q^2)F_{VDM}(P^2) \left[A + \frac{B}{W} \right] \quad (1)$$

where W is the invariant mass of the $\gamma\gamma$ system and Q^2 and P^2 are the absolute squared masses of the two virtual photons. The values $A = 275$ nb and $B = 300$ nb·GeV/ c^2 were used [14], which are about 10% larger than those in the standard formula [13]. This type of parametrization has already been used by previous experiments [2,3].

The quantity F_{VDM} is the generalized VDM form factor [15]

$$F_{VDM}(Q^2) = \sum_{V=\rho,\omega,\phi} r_V \frac{1 + Q^2/4m_V^2}{(1 + Q^2/m_V^2)^2} + \frac{0.22}{1 + Q^2/m_0^2} \quad (2)$$

with $m_0 = 1.4$ GeV/ c^2 and where m_V denotes a vector meson mass and r_V is related to the vector meson coupling to the photon. The last term describes the contribution from the radial excitations of vector mesons.

In the simulated events the multihadronic final-state was generated from a $q\bar{q}$ pair, with a limited- p_T quark distribution $d\sigma/dp_T^2 \simeq \exp(-5p_T^2)$ in the $\gamma\gamma$ centre-of-mass system using the PLUTO tuned parameter [2].

The other contributions are treated using leading order QCD factorization: a hard scattering subprocess gives the dominant scale p_T^2 , taken also as the factorization scale. The photon participates by direct coupling to quarks or to a quark or a gluon produced through a QCD evolution starting from a bound state or to a perturbative $q\bar{q}$ -pair state. There are three terms: the direct term of Figure 1c (a QPM generator was used to describe this interaction term, analogous to the QED process $ee \rightarrow ee\mu\mu$ but with quark masses), the singly-resolved photon contribution of Figure 1d and the doubly-resolved photon contribution of Figure 1e (both of which were described by the QCD-RPC model). Since the hard scattering subprocesses are considered as perturbative within QCD-RPC, a cut,

p_T^{min} , on the transverse momentum of the outgoing partons has to be specified in order to separate them from the non-perturbative contribution and avoid double counting (the p_T^{min} cut was not implemented for QPM). Unfortunately, there is still no model which completely removes this problem. As mentioned above, the quarks and gluons are emitted from a photon through QCD evolution, starting from either a point-like or a bound-state coupling. Total separation implies the use of another quark transfer cut-off (p_T^0) at the first quark-pair creation level as shown in previous papers [16,17] and in a more recent global approach [18]. Since the existing quark and gluon parametrizations do not allow such a distinction, in the present study the outgoing partons are assumed to participate in high- p_T jet production, while the spectator partons produce “beam-pipe” jets. The latter were generated along the direction of the incoming quasi-real photons.

In the present study the values of p_T were found greater than $1.5 \text{ GeV}/c$, *i.e.* much larger than the magnitude of the mass of the virtual photons. Within the QCD-RPC model, the p_T^2 of the outgoing partons of the hard scattering subprocess in multi-jet production (which is always greater than a required minimum value $(p_T^{min})^2$) probes the structure of one photon in singly-resolved processes, or both photons in doubly-resolved processes [19]. In this approach the two photons need to be considered as quasi-real.

Thus the main features of the two-photon mechanism used to describe the data are the following. Most secondary particles from the $\gamma\gamma$ events are produced at small polar angles, and only some of the particles of the final system are actually detected. The resolved photons produce beam-pipe or “remnant” jets, which may mix with decay products of the low- p_T central system. The presence of jets of (moderately) high p_T at large angles forms a signature for the isolation of the hard scattering subprocesses from the dominant diffractive dissociation contribution.

Many partonic density functions of the photon are available, but since they are extracted from deep inelastic $e\gamma$ scattering at high Q^2 they cannot always be used to describe hard scattering processes at relatively low $(p_T/c)^2$. Only leading order parametrizations have been considered here. *A priori* each of these parametrizations is associated with a specific value of p_T^{min} , constrained by the description of the visible total cross-section and can be tested directly against the data. This approach, as shown below, indicates the distinctive requirements for a successful parametrization. In particular, hard parton distributions will produce more high- p_T jets in the central region while soft distributions lead to more energy deposition in the jets from the photon remnants.

These three models (VDM, QPM and QCD-RPC) were implemented in the TWOGAM generator [20] used for generating $\gamma\gamma$ events, requiring one lepton to be scattered towards the VSAT polar angle region (see Section 3). No selection was applied to the other lepton, since it mainly goes inside the beam pipe. The generated events were then fragmented using the JETSET 7.3 [21] model. In the simulation of the VDM model, the JETSET parameter σ_q , describing the dispersion of the transverse distribution of primary hadrons within a jet, was set to $450 \text{ MeV}/c$ in order to take into account the bound-state origin of the quarks [22].

To take into account the influence of the magnetic field of DELPHI and superconducting quadrupoles on the scattered leptons, specially developed programs were used for fast selection of events with a lepton hitting a VSAT module, as well as for simulating and reconstructing the resulting VSAT response. These programs have been extensively used in VSAT luminosity studies. The hadronic parts of the events were simulated and reconstructed by standard DELPHI programs.

Simulations were performed separately for the VDM, QPM and QCD-RPC processes. Five parametrizations of the parton density function of the photon were chosen for sim-

ulation [23]: the Gordon-Storow (GS) [24] model, the Drees-Grassie (DG) [19] model, the Duke-Owens (DO) [25] model and two of the Levy-Abramowicz-Charchula models (LAC1 and LAC3) [12].

In this analysis, the Q^2 values measured by the VSAT are of the order of $0.1 (\text{GeV}/c^2)^2$, much lower than the $(p_T/c)^2$ of the jets (for all the QCD-RPC models, the $(p_T^{min}/c)^2$ values are greater than $2 (\text{GeV}/c^2)^2$, so that the simulation can be made as for a no-tag case.

This would not be true for Q^2 values around $1 (\text{GeV}/c^2)^2$ since there is still no theoretical description of $\gamma\gamma$ collisions in the region where Q^2 and $(p_T/c)^2$ are of the same magnitude. The total cross-section could, in principle, be unfolded from the data with the great advantage that the uncertainty in the VDM form factor extrapolation would be small.

3 Apparatus and Event Selection

A detailed description of the DELPHI detector can be found in ref. [26]. Only the DELPHI components relevant to the $\gamma\gamma$ -event analysis (charged-particle tracking and electromagnetic calorimetry) are briefly described here. The VSAT sub-detector [27] is described here somewhat more thoroughly.

A right-handed coordinate system is used in this paper. The z -axis lies along the electron-beam direction and the y -axis is defined to point vertically upwards with the origin at the nominal beam-crossing point. The polar angle θ is measured with respect to the z -axis, and the azimuthal angle ϕ is measured with respect to the horizontal plane. Charged-particle tracks are measured in a 1.2 T magnetic field parallel to the beam axis by three cylindrical tracking chambers: the Inner Detector (ID), covering polar angle from 30° to 150° at radii 12 to 28 cm, the Time Projection Chamber (TPC), the main tracking device, covering polar angles from 20° to 160° and radii between 35 and 111 cm and the Outer Detector (OD) covering polar angles from 43° to 137° at radii between 198 and 206 cm. Using the ID, TPC and OD, the momentum resolution is $\sigma(p)/p = 0.0015p$ where p is expressed in GeV/c .

Tracking in the forward ($11^\circ < \theta < 33^\circ$) and backward ($147^\circ < \theta < 169^\circ$) regions is performed by two pairs of Forward drift Chambers (FCA and FCB) in the end-caps.

Electromagnetic energy is measured in the barrel region by the High density Projection Chamber (HPC) and in the forward and backward regions by a Forward Electro-Magnetic Calorimeter (FEMC), consisting of 4522 lead-glass blocks in each end-cap and covering the polar angular regions $10^\circ < \theta < 36.5^\circ$ and $143.5^\circ < \theta < 170^\circ$. The HPC has nine layers of lead and gas covering polar angles from 43° to 137° and radii between 208 and 260 cm.

Hadron shower energies are measured by combining the measurements from the HAdron Calorimeter (HAC) covering polar angles from 10° to 170° , and from the electromagnetic calorimeters.

The Very Small Angle Tagger (VSAT) is the fundamental tool in this analysis, as it is used to tag the scattered lepton from the $\gamma\gamma$ interactions. The VSAT consists of four rectangular electromagnetic calorimeter modules, each 5 cm high, 3 cm wide and 24 radiation lengths deep. The modules consist of 12 tungsten absorbers, each two radiation lengths thick, each followed by an energy sampling silicon plane, giving an energy resolution of $35\%/\sqrt{E(\text{GeV})}$. Three silicon-strip planes are placed around the longitudinal maximum of the electromagnetic showers (between five to nine radiation lengths inside the modules), two measuring the horizontal position and one the vertical position. Each

strip is 1 mm wide, giving a reconstructed position resolution of 200 μm . The four modules are placed horizontally on both sides of the beam pipe at ± 7.7 m along the beam axis from the DELPHI interaction point (see Figure 2a for definitions). At this point the beam pipe changes from a cylinder of 16 cm diameter to an elliptical form of 16 cm vertically by 12 cm horizontally. The modules are placed after the LEP superconducting quadrupole magnets, resulting in scattered leptons being focused vertically and defocused horizontally. The magnitude of this effect is inversely proportional to the lepton energy, resulting in a VSAT polar angle coverage from 4 to 8 mrad for the $\gamma\gamma$ case.

The quality of the event triggering system is very important in $\gamma\gamma$ data taking due to the low multiplicity of the final state, the low particle momenta and the particles mainly being boosted into low polar angles. The VSAT takes no part in the event triggering, which is done entirely on the hadronic part of the $\gamma\gamma$ events. The main component of the barrel part of the trigger for this analysis is the coincidence of ID and OD signals, while the forward trigger is based on the coincidence of signals from the FCA, FCB and TPC sub-triggers. The component from neutral particles contributes negligibly to the $\gamma\gamma$ trigger rate.

Because of the forward-boosted shape of the $\gamma\gamma$ events, the most important part of the event triggering is performed by the forward trigger. Information on all trigger components was recorded for the $\gamma\gamma$ events in order to test the forward trigger performance. The single-track efficiency was then calculated from the redundancy of the independent triggers, leading to a trigger efficiency of more than 95% for the final $\gamma\gamma$ event sample, selected as described below.

The multiplicity and energy of charged particles formed the basic criteria for selecting $\gamma\gamma$ hadronic events. Charged particles were accepted if the following criteria were met:

- momentum larger than 0.4 GeV/ c ;
- polar angle from 20° to 160° ;
- radial projection of the impact parameter relative to the interaction point less than 4 cm;
- projection of the impact parameter along the beam direction less than 10 cm;
- relative error on momentum measurement less than 1.

All calorimetric information was included in the event selection to reject the background from Z^0 decays. Taking into account the sensitivity, stability and noise performance of the calorimeters, the following minimum-energy thresholds were chosen: 0.5 GeV for the FEMC and HPC neutral clusters, and 1.5 GeV of reconstructed energy for unlinked calorimetric showers in the HAC.

In order to select $\gamma\gamma$ events the following criteria were applied to the hadronic system in each event:

- (a) at least three charged particles in the event;
- (b) total energy of the charged particles less than 12 GeV;
- (c) total visible energy less than 20 GeV;
- (d) invariant mass in the range between 3 and 11 GeV;
- (e) net charge not more than 2;
- (f) thrust value less than 0.999.

In addition the tagged lepton was required to have:

- (g) VSAT measured energy larger than 20 GeV;
- (h) VSAT (θ, ϕ) -position reconstructed.

Criterion (a) selects hadronic final states, while criteria (b), (c) and the upper limit of (d) suppress Z^0 decay background. The lower limit of criterion (d) suppresses the resonance region of the $\gamma\gamma$ interaction and, together with criteria (e) and (g), the beam-gas back-

ground. Criterion (f) rejects the bulk of τ pairs from $\gamma\gamma$ collisions leaving a negligible remaining contribution. Criteria (g) and (h) select well-measured leptons with very low Q^2 .

4 Background Rejection

Two million Z^0 hadronic events were generated and the events which could give an energy deposition in the VSAT greater than 10 GeV were fully simulated and reconstructed. Since no event was left after the selection criteria were applied, the background to the VSAT-tagged $\gamma\gamma$ events came from purely random coincidences between two independent events: an off-momentum beam electron hitting a VSAT module and some other physical event producing a hadronic system in the DELPHI detector. The probability of such coincident, but independent, events is given by the product of the individual probabilities of accepting off-momentum electrons in the VSAT and hadronic systems in DELPHI. The hadronic system mainly came from untagged $\gamma\gamma$ events, *i.e.* events with both the scattered electrons going undetected into the beam pipe. Also the decays of Z^0 , especially those involving τ particles, as well as beam-gas interactions also contributed to the background, though to a much smaller degree.

The probability of accepting off-momentum electrons in the VSAT was estimated by studying a specially selected hadronic Z^0 event sample with a strong signal in DELPHI (*i.e.* events having many charged particles, high invariant mass and large energy deposition). According to simulation such events should have given no signals in the VSAT, but some nonetheless were found in the data. The dominant part of this background, 86%, occurred in the two VSAT modules on the outer side of the LEP ring. The results are shown in Figure 2, which shows the VSAT distributions for these off-momentum events in a) azimuthal angle ϕ , b) polar angle Θ (both reconstructed in the interaction point by track extrapolation through the DELPHI and quadrupole magnets) and c) energy normalized to the beam energy. The different energy spectra for the VSAT inner and outer modules correspond to different off-momentum beam components of the LEP machine. The distributions for the outer modules are narrower than for the inner modules, especially for ϕ (shifted by π for the outer modules). This fact was used to introduce cuts in ϕ for the outer modules 1 and 3 ($-0.30 < \phi_1 - \pi < 0.14$ and $-0.38 < \phi_3 - \pi < 0.14$) in order to reject the majority of the off-momentum electrons. No cut was applied for the inner modules. The ϕ selection rejects 66% of all the incident off-momentum electrons.

The final probability of purely random coincidence events passing all the single tagged $\gamma\gamma$ event selection criteria corresponds to a background level of 3.8% in the final $\gamma\gamma$ -event sample.

5 Results

Using the VDM, QPM and QCD-RPC models to generate simulated events, only events which passed all the selection criteria described above were used in order to understand the kinematics of the VSAT tagged $\gamma\gamma$ events. Figure 3a shows the absolute masses of the tagged ($Q^2 = -q_1^2$) and the untagged ($P^2 = -q_2^2$) photons (see also Figure 1a). P^2 is strongly peaked towards very low values since the untagged leptons generally do not leave the beam pipe. Q^2 for the VSAT tagged events is very small ($\langle Q^2 \rangle = 0.06$ (GeV/ c^2)²), but still much larger than P^2 . There is no significant difference between the generated and reconstructed Q^2 distributions.

The remaining part of this section deals with comparisons between data and full simulation. The final data sample consisted of 491 events.

The events of the QCD-RPC models were initially generated with low values of p_T^{min} which were then increased until, finally, the total VDM+QPM+(QCD-RPC) simulation reproduced the observed number of data events. The VDM contribution was allowed to vary by $\pm 10\%$ in comparison with the “standard” one defined by formula (1). This was done in order to estimate the variance of the p_T^{min} values due to the influence of the VDM cross-section uncertainty. From Table 1 it can be seen that the variation of p_T^{min} with the VDM contribution is rather smooth for all the parametrizations used and also that the variations are not significant, being of the order of 5%.

QCD-RPC Model	GS	DG	DO	LAC1	LAC3
+ 10% VDM	2.04	1.64	1.67	2.25	3.07
+ 5% VDM	1.99	1.60	1.63	2.21	3.01
“standard” VDM	1.95	1.56	1.60	2.17	2.95
- 5% VDM	1.92	1.52	1.56	2.14	2.90
- 10% VDM	1.88	1.48	1.52	2.10	2.83

Table 1. Final p_T^{min} values in GeV/c for the QCD-RPC models studied.

In each case there were at least 6000 finally selected simulated events. To provide comparable conditions for each QCD-RPC parametrization, the differences in the final number of events were less than $\pm 1\%$ after all the cuts applied.

Statistical comparisons between the data and simulated distributions were performed using two independent methods: the well-known χ^2 -test and the Kolmogorov test [28]. This algorithm, though not as well-known as the χ^2 -test, has some advantages. It does not require a minimum number of entries per bin, which is useful for testing the rather small statistical data sample available. It also takes into account the signs of the differences between distributions rather than just the magnitude, which makes the test sensitive to consecutive deviations of the same sign. The measure of compatibility between two distributions is given as a probability, \mathcal{P} . A probability close to 100% indicates very similar histograms, and a value near zero means that it is very unlikely that the two arose from the same parent distribution. The disadvantage of the Kolmogorov test is that the returned probability \mathcal{P} for binned data could be overestimated.

The χ^2 for each distribution was defined by the formula

$$\chi^2 = \sum_{i=1}^{N_{ch}} \left[\frac{R_{data}(i) - R_{MC}(i)}{\sqrt{\sigma_{data}^2(i) + \sigma_{MC}^2(i)}} \right]^2 \quad (3)$$

where $R_{data}(i)$ and $R_{MC}(i)$ are the contents of bins i , $\sigma_{data}(i)$ and $\sigma_{MC}(i)$ are their errors, and N_{ch} is the number of histogram channels with a content greater than 20, used as a number of degrees of freedom.

The distribution of the invariant mass of the hadronic system, W , is shown for the data and for the VDM+QPM model and VDM+QPM+(QCD-RPC) models in Figures 3b and 3c, respectively. It is clear that the VDM+QPM model cannot provide a good description of the observed invariant mass distribution. Even when the VDM cross-section was allowed to vary across a wide range either to fulfill a total cross-section or to tune satisfactorily the description of the shape, the resulting probability \mathcal{P} was very small indeed for both Kolmogorov and χ^2 -tests (indicated as 0. in Figure 3b). However, adding the QCD-RPC component with any structure function parametrization other than LAC3

gave a good description of the data, as illustrated by \mathcal{P} with the best model on top and the worst one on bottom in Figures 3c and 3d. The clear evidence for the need of the QCD-RPC contribution is also illustrated in Figure 3d, for the tagged energy fraction.

To illustrate the compatibility of different simulated models with the data, plots of standard event variables and inclusive distributions are presented in Figure 4, while some plots of typical variables from an analysis using jets are shown in Figure 5. Jet reconstruction was performed by using the Lund cluster algorithm [21] with a maximum distance d_{join} of 1.4 GeV/ c , below which two clusters are allowed to join into one.

From the \mathcal{P} values given on plots, some parametrizations cannot provide a satisfactory description of all these distributions, as low probabilities are obtained for some of them. Very similar results with comparable probabilities were obtained using the χ^2 -method. In agreement with results from the AMY Collaboration [3], the LAC3 model can be rejected at this stage as the worst model, giving small values of \mathcal{P} for several distributions. The physical reason for this is known: the LAC3 parametrization gives an extraordinarily large gluon density in comparison with other models.

Further attempts to distinguish between the remaining parametrizations were performed using an overall χ^2 -test, when several distributions were taken into account simultaneously. The invariant-mass, tagged-energy and jet transverse-momentum distributions were chosen as the most important (and not very closely correlated) variables. The tests were also performed with a $\pm 10\%$ variation of the VDM cross-section. The results are shown in Table 2.

QCD-RPC Model	GS	DG	DO	LAC1
+ 10% VDM	1.39	0.07	0.02	4.29
+ 5% VDM	3.52	0.31	0.08	3.82
“standard” VDM	7.05	0.88	0.20	2.32
- 5% VDM	9.53	2.35	0.31	1.17
- 10% VDM	11.94	3.79	0.36	0.32

Table 2. Probabilities (%) from the overall χ^2 -test for the QCD-RPC models studied. The number of degrees of freedom is equal to 16.

The GS, DG and DO QCD-RPC models behave similarly, their agreement with data becoming better when the VDM contribution is decreased, whereas the LAC1 model follows the opposite trend. The probability of the tests for the GS parametrization, starting from the “standard” VDM cross-section, rises above the 5% level. The LAC1 comes close to 5% when the VDM cross-section is 10% higher than the “standard”, the same being true for the DG model when the VDM cross-section is lowered by 10% from the “standard”. The DO model should be rejected because the overall probability is always very low. These results are in agreement with the previous no-tag analysis from DELPHI [5].

6 Conclusions

For the first time at LEP, very low Q^2 single tagged events have been studied and compared with VDM+QPM+(QCD-RPC) models. The data are consistent with the predictions for quark and gluon density functions provided the QCD-RPC model is used with the GS parametrization. The LAC1 and DG parametrizations are also capable of providing a satisfactory description of the data after tuning of the VDM contribution. The DO and LAC3 parametrizations do not adequately describe the data.

Acknowledgements

We are greatly indebted to our technical collaborators and to the funding agencies for their support in building and operating the DELPHI detector, and to the members of the CERN-SL Division for the excellent performance of the LEP collider.
