¹*LPC Caen, ENSICAEN, Université de Caen, CNRS/IN2P3, Caen, France*

In this work, we studied the emission yields, decay times and coincidence resolving times (CRT) of two gases, nitrogen (N_2) and tetrafluoromethane (CF_4), used for particle detection in the context of fission products measurement. The set-up was made of an ionization chamber and two photomultiplier tubes (PMTs) placed front-to-front on each side of the active zone of the chamber. Using the photomultiplier tubes, the number of photoelectrons (phe) converted at the photocathodes from the scintillation processes in each gas were quantified and the scintillation time spectra were recorded. An scintillation emission yield of 24 phe MeV^{-1} with a decay time of $\tau_d = 2.5$ ns in N_2 , and 225 phe MeV^{-1} with $\tau_d = 6.2$ ns for CF_4 , have been measured. With our set-up, the coincidence resolving time (σ values) between the two PMTs have been measured at 1.4 ns and 0.34 ns for N_2 and CF_4 respectively, using alpha particles.

INTRODUCTION

Ionisation chambers (ICs) have been widely used in many fields of nuclear physics due to their good energy resolution, large acceptance and low production cost. Currently, the SPIDER [1] and FALSTAFF [2] projects are devoted to fission studies and intend to use ionization chambers together with two additional Secondary Electron Detectors (SED) in order to measure the energy and the velocity of one fission fragment. They thereby both rely on the determination of the fragment Time-of-Flight (ToF) between SED foils, made of carbon coupled to Micro-Channel Plates (MCP) for SPIDER and mylar associated with micromegas gaseous chambers for FALSTAFF. The energy of the fragment being measured by the IC. In those projects, high energy and time resolutions are required to obtain a good mass identification resolution. For instance, the framework of the FALSTAFF project at the NFS[29] facility, requires a 1% energy resolution and a 150 ps time resolution FWHM to be able to measure fission fragments masses with a 2 units resolution [2]. However, if ICs can ensure a 1% energy resolution, difficulties arise in obtaining a good event energy reconstruction through the lack of knowledge of the energy losses encountered by the fission fragments in the two SED foils and the IC entrance window.

To improve the reconstruction performances of the detection system, we have studied the possibility to replace one SED by the fast triggering signal obtained from the scintillation processes induced in the gas of the IC. This system could find applications in neutron beam energy monitoring by ToF like systems [3] for instance in the case of neutron cross sections measurements where the ionisation chamber is used as an active target [4].

Many works reported the good transport properties of electrons in tetrafluoromethane (CF_4) compiled in [5]. CF_4 scintillation properties [6–10], and those of nitrogen (N_2) [3, 11], are already well established. These two gases were thereby investigated as good candidates for

use in the scintillating ionisation chamber (SIC). In this paper, we propose to study their scintillation properties relevant for use in our IC (i.e. emission yields and decay times) as well as the energy and timing performances of the resulting SIC. Those measurements ought to be integrated in a Monte-Carlo simulation for the detection system oncoming evaluations.

MATERIALS AND METHODS

Experimental set-up

Fig. 1 shows the apparatus used to study the primary scintillation yields and decay times of N_2 and CF_4 . In the gas vessel, the active volume of $5 \times 5 \times 5$ cm³ of the ionization chamber was delimited by field shaping wires, a cathode and a Frish Grid (FG). The high voltage of 1182 V applied between the cathode and the FG made a 236 V cm⁻¹ electric field in the active volume. The field shaping wires were used to obtain a constant electric field from the cathode to the FG, ensuring a constant drift velocity of the charges. The field between the grounded anode and the FG with a distance of 0.35 cm was set to 337 V cm⁻¹ in order to increase the transparency up to 95% of the incoming electrons from the active volume. This value was obtained by Monte Carlo simulation based on electric field maps calculated using a Finite Element Method software (FreeFEM++ [12]). The inefficiency ($\sim 4\%$) of the grid was estimated by calculations as in [13].

The radioactive source used for the measurements was placed beneath the cathode inside the ionizing volume in order to reduce energy losses. The source was made by electro-deposition on a stainless steel disc of three radioactive elements, ²³⁹Pu, ²⁴¹Am and ²⁴⁴Cm, emitting α particles with mean energies of $E_\alpha = 5.14, 5.44, 5.8$ MeV respectively, in 2π sr within the active volume.

The two photomultiplier tubes, R-2059 from Hamamatsu corp., were located front-to-front on both side of

FIG. 1: Sketch of the experimental set-up.

the active volume. The wavelength at maximum emission of N_2 was evaluated at 390 nm [14]. According to [8], CF_4 exhibits two main components at ~ 300 nm and ~ 630 nm. The scintillation emission spectra of the gases matches then the PMTs spectral response which ranges from 160 to 650 nm from the manufacturer data sheets, with a peaked sensitivity measured at 320 nm [15].

The PMTs entrance windows were used as sealing interfaces with the gas while leakages were avoided using torus joints. The high voltages were set to -2200 V corresponding to an intrinsic gain of approx. 10^6 .

The gases, nitrogen (from Air Liquide) and tetrafluoromethane (provided by Messer UHP), were injected in the active volume at a 1 atm pressure. The detector operates in gas flow with a debit of ~ 0.25 L h^{-1} .

The electric signals from the PMTs were converted into charge integrating channels (QDCs) using the FASTER in-house built acquisition system [16]. Each acquisition input was also able to measure the time of arrival of the signals using a 7.8 ps time-to-digital converter (TDC) fed by a digital constant fraction discriminator (dCFD). The signal coming from the IC passed through a charge pre-amplifier with a τ_{RC} of 30 μs and was acquired using a third input used as an amplitude-to-digital converter (ADC) with a 2 ns time stamp. Each input was recorded individually and the analysis was performed off-line. The signal processing were chosen to optimize the timing resolutions for the PMTs, especially on the dCFD, as well as for the energy resolution of the IC.

IC Energy resolution

The IC detected the signals induced by secondary electrons resulting of the interactions of α particles with the gas molecules. The signal was processed by a numerical algorithm that mimics a spectroscopic amplifier. The shaping time for N_2 was set to 6 μs and 2 μs for CF_4 , corresponding to a different electron drift velocity of about 0.5 cm μs^{-1} for N_2 [17] and 6.0 cm μs^{-1} for CF_4 [5].

The ranges of the α particles in the different gases have been estimated using Geant4 simulations and found to be around 35 to 42 mm and 15 to 20 mm for N_2 and CF_4 respectively. Due to the uncollimated source, α particles

with a large emission angle may not deposit their entire kinetic energy within the active volume in the case of N_2 .

For CF_4 , the energy resolutions were extracted from the energy distribution using three Gaussian fits. A background distribution taken as a 9th order polynomial function was added to take care of the above mentioned situation for the N_2 energy distribution.

PMT single photoelectron response (SPE)

Before measuring the scintillation properties of the gases, we performed a calibration of the PMTs in order to obtain the single photoelectron response (SPE) in terms of QDC values. For that, the signals from the PMTs without the source and in ambient air, were acquired in two different time windows. The first time window (QDC₁) of 35 ns wide was set around the zero time (-15 ns to 20 ns) given by the triggering of the PMT of interest. The trigger level was set to 3σ above the electronic noise (~ 0.8 mV). The second one (QDC₂) delayed by 45 ns from 30 to 65 ns, was used to obtain non-correlated signals. The width of the windows has been chosen to exceed more than 10 SPE decay time of the PMT, estimated to be around 3 ns on the signal observed on the oscilloscope. This procedure was done for both PMTs.

Fig. 2 gives the distributions of QDC₁ and QDC₂ for PMT₁. The number of events is normalized by the total number of counts measured during the entire acquisition. QDC₂ shows in black the distribution of the pedestal and the noise of the first dynode, described by a Poisson distribution and an exponential decay behaviour [18]. This plot gave the lower limit for the SPE signals at 1500 QDC channels. By fitting the distribution of QDC₁ corresponding to 1 photoelectron (phe) induced by thermal agitation on the photocathode with a Gaussian curve (solid red line), we obtained the correspondence of the SPE response as the average value of 2200 QDC channels. Multiple photoelectrons distributions (≥ 2) were not taken into account in the measurement of the single phe.

Scintillation decay times

The effective decay time of the scintillation processes were measured for up to 100 ns considering only one decay component.

To measure the decay time spectra, we used a somewhat similar method as given in [19]. One PMT (PMT₁) was used to trig to the single photoelectron level. Its entrance window has then been partially covered in order to reduce the probability to detect two phe from a scintillation event below 0.1%, regarding the approximate scintillation light yield, PMTs detection efficiencies and

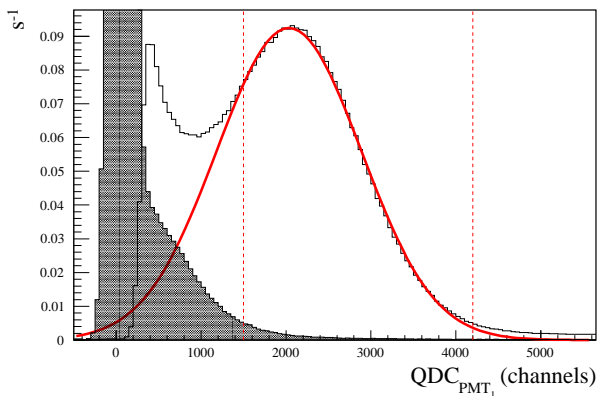

FIG. 2: SPE calibration spectrum for PMT₁, QDC₁ is plotted unfilled and QDC₂ is black filled. The solid red line correspond to the Gaussian fit of one photoelectron. The vertical dashed lines show the fit intervals.

Poisson statistics. Each PMT output was recorded individually. When put in coincidence with a time window of 100 ns, the second PMT (PMT₂) detected the scintillation photons corresponding to the energy deposited by the alpha particles. The arrival time of the PMT₁ signal (‘stop’ detector), gave the time difference between the two. The time difference was then plotted to obtain the scintillation time spectra for each gas.

The decay time of the scintillations were extracted using the procedure described in section .

Scintillation emission yield

The scintillation emission yields of the gases have been measured in terms of photoelectrons converted by the PMT photocathodes. The tri- α source was placed as mentioned above and the gas flowed at 1 atm pressure. The electronic triggers on the PMT signals have been set to 3σ above the electronic noise level. The acquisition was done regardless the triggering PMT and data were set in coincidence or in anti-coincidence afterwards in post-processing analysis using their time stamps. The coincidence measurements relate to the scintillation processes issued by α particles from the source while in anti-coincidence, background events can be measured.

The integration time window for every triggered event was set to 30 ns for N₂ and 40 ns for CF₄, assuming an approx. 2.5 ns and 6.3 ns decay time for N₂ and CF₄ respectively. The time windows represented then the integration of more than 95% (3 decay times) of the signals and allowed to avoid after-pulses considerations in the charge integration. Those appeared at ~ 300 ns, ~ 600 ns and $\sim 2 \mu\text{s}$ [20] after the main signal in the anti-coincidence events.

Fig. 3 shows an example of the energy spectrum mea-

sured for CF₄ using the tri- α source. The spectra measured shows two components: one in coincidence in the two PMTs showing the primary scintillation induced by α particles, and a second corresponding to after-pulses in the PMT.

FIG. 3: Distribution of photoelectrons in one PMT induced by α particles (black line histogram) for CF₄ at atmospheric pressure, the dashed line filled (red) histogram corresponds to coincidence between the two PMTs and the filled with solid lines (blue) histogram corresponds to anti-coincidence. The dot filled (black) histogram corresponds to background acquisition.

The sum of the two PMTs signals for the coincidence events only were used to extract the scintillation light yields for the two gases. For nitrogen, due to a degraded IC energy resolution and a slower electron drift velocity, no information from the IC was used to help in the selection of the three different α interactions in the gas. For the CF₄ gas however, a correlation spectrum between the recorded IC energy and the sum of the two PMTs signals was made. Each α distribution was selected separately and the three spectra of the sum of the PMTs signals were fitted with a Gauss distribution to extract their mean and σ values.

The corresponding light yields of each gas were then corrected for the geometrical factors and using the PMTs SPE responses. The geometrical factors, corresponding to the number of photons incident on the PMTs windows divided by the total number of emitted photons, of $(3.1 \pm 0.2)\%$ and $(3.6 \pm 0.2)\%$ for N₂ and CF₄ respectively, have been estimated by Monte-Carlo simulations using Geant4-9.5.0 [21]. A detailed description of the simulation is presented in section .

System Coincidence resolving time

Coincidence resolving time measurements were conducted for the two gases using the two PMTs in coincidence.

The coincidence time window of 100 ns was used as well as the appropriate integration time windows for the corresponding gases. Correlation plots were made, after conversion of the QDC channels into SPE, between the number of SPE collected by each PMT. In these distributions, a selection was made accounting for the correlated events. For those events, the time difference of arrival between the two PMTs signals was then plotted and fitted with a Gaussian curve, the coincidence resolving time being the extracted σ values.

System simulations

Monte Carlo simulations were performed for the detection system with two different goals. A first goal, was to accurately extract the scintillation time characteristics of the two gases using phenomenological behavior of the PMT electronic response. The second goal was to build the detection system in Geant4-9.5.0 to be able to perform further simulations where the system intrinsic properties were to be evaluated experimentally. Those two approaches are detailed below.

Scintillation decay time evaluation

To extract the parameter τ_d of the scintillation process, a Monte-Carlo simulation was used, taking into account the scintillation rise and decay times, the electronic response of the PMTs and triggering system. A number N of photoelectrons following the time distribution given by $f_{sc}(t)$ in eq. 1 with τ_r the rising time of the system, was generated proportional to the gas emission yield previously measured and the PMTs detection efficiencies. This method was mandatory to match the technique used for measuring the scintillation decay time, where one has to trig on the primary scintillation signal of a PMT while putting in coincidence the triggered signal from one photoelectron of the other PMT. The electrical signals were computed by convolving the photoelectrons temporal distributions with an assumed Gaussian shape of the single photoelectrons from the PMT and the response $h(t)$ of the read-out circuit given in eq. 2. The circuit was taken as a low-pass filter of the first order with parameters R and C , respectively the impedance and the capacitance, chosen to fit its experimental behaviour [22].

$$f_{sc}(t) = \exp\left(-\frac{t}{\tau_d}\right) - \exp\left(-\frac{t}{\tau_r}\right), \quad (1)$$

$$h(t) = \frac{1}{C} \exp\left(-\frac{t}{RC}\right) \quad (2)$$

The signals passed then through dCFDs, to extract for one PMT, the triggering time of the scintillation processes, t^{sci} , and the single phe triggering time, t^{phe} , of the other PMT. Their time difference was then plotted. The parameters τ_r and τ_d were changed until they minimized the χ^2 values between the simulated time difference spectra and the experimental ones. Extraction of the rising time was made possible using this method. However, a relevant value would require taking care of all possible parameters (e.g. the range of the α particles, the transit time spread of the PMTs, etc...) which are mainly out the scope of this paper. In consequence, the rising time of the scintillation will not be presented here.

This method was used instead of the traditional exponential fitting procedure in order to take into account for our intrinsic system properties without having to deconvolve them afterwards.

Geant4 system simulations

The detection system was simulated using Geant4-9.5.0 to transport the optical photon from the different sources along the α range to the photocathode of the PMTs. The full geometry of our system was implemented including the field shaping wire, the FG and their supports. The tri- α source was modeled by a cylinder at the surface of the aluminum support, the direction emissions were randomized in the hemisphere facing the active volume. Geant4 comes with a full implementation of electromagnetic processes (using the *em_option3* physics package) for taking care of the α particle interactions in the gas. The simulation of the scintillation light emission was as follows. For each α particle energy deposition, the simulation generated a number of photons proportional to the gas emission yields, emitted isotropically at the wavelength at maximum emission, with two components in the case of CF_4 . All the system surfaces optical behaviors were taken into account using the *unified* model included in Geant4. The photon passing through the PMTs entrance windows were converted in post-analysis treatment into photoelectrons using the corresponding measured quantum efficiencies found in [15]. A simulated PMT signal and read-out electronic was then generated using the same procedure as described in section .

The resulting calculations have been compared with the experimental data concerning the coincidence resolving times between the two PMTs.

RESULTS AND DISCUSSION

IC energy resolution

Fig. 4 shows the energy distributions of the tri- α source for the two different gases. The energy resolution of each

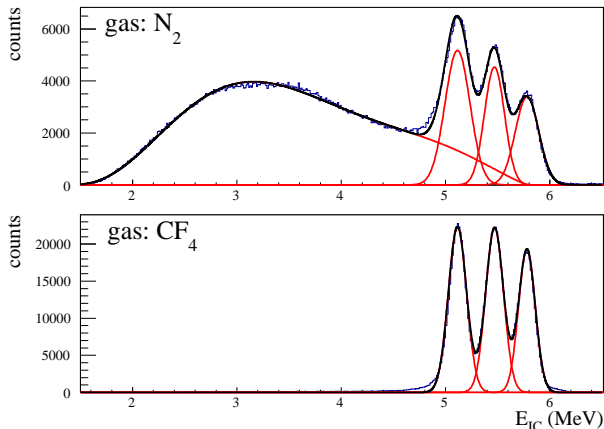

FIG. 4: Energy spectra obtained from the ionisation chamber for the two gases with the tri- α source.

gas is extracted by fitting each peak with a Gauss distribution plus a background distribution in the case of N_2 . Table I presents the different resolutions obtained for our energy measurements.

The energy resolution obtained with CF_4 is slightly better than for N_2 with a minimum value of 3.2% measured on the 5.8 MeV ^{244}Cm α emission. This difference can be explained by a Fano factor smaller in the case of CF_4 compared to N_2 with respectively $F \approx 0.2$ [23] and $F \approx 0.28$ [24]. Nevertheless, the energy resolutions allow the three different peaks to be clearly visible in both gases.

TABLE I: Energy resolution of the ionization chamber referred as the FWHM in keV of each α peak for the different gases. In parentheses, the relative energy resolution in %.

E_α (MeV)	N_2	CF_4
5.14	336. (6.5%)	204. (4.0%)
5.44	270. (5.0%)	200. (3.7%)
5.80	250. (4.3%)	188. (3.2%)

Scintillation decay times and emission yields

Fig. 5 shows the measured (black solid lines) and simulated (red dashed lines) scintillation time spectra obtained for N_2 and CF_4 gases.

Decay times are respectively extracted at (2.5 ± 0.5) ns and (6.2 ± 0.8) ns for N_2 and CF_4 with χ^2/ndf values of 1.45 and 1.1. Those results are in good agreement with previously published ones [9, 10] and show that N_2 is 2.5 times faster than CF_4 .

Fig. 6 shows the sum of the number of photoelectrons collected by each PMT for the two gases. In the case of N_2 , no selections were made on the IC energy to select

FIG. 5: Experimental time scintillation spectra for N_2 and CF_4 gases and the simulation used to extract the timing properties (red dashed lines).

individual α emitter. The number of photoelectrons corrected from the detection efficiencies for N_2 , corresponds thereby to a mean value of 24 phe MeV^{-1} with a standard deviation of 10 phe MeV^{-1} .

In the case of CF_4 , the selection of each α emitter using the IC energy was made and fitted using a Gauss distribution (Fig. 6(b)). The mean phe values are 41 ± 5 , 44 ± 5 and 46 ± 5 for 5.14, 5.44 and 5.8 MeV α energies respectively, corresponding to a mean number of photoelectrons corrected for the detection efficiencies of $(225 \pm 28) \text{ phe MeV}^{-1}$. Using the measured quantum efficiencies given in [15] for our PMTs of 25% for N_2 and 19% for a composition of the two components of CF_4 (evaluated at approx. 2/3 and 1/3 for the 300 and 630 nm emissions at a 1 atm pressure [7]), photon yields of $(96 \pm 40) \text{ ph MeV}^{-1}$ for nitrogen and $(1184 \pm 47) \text{ ph MeV}^{-1}$ for tetrafluoromethane are extrapolated. Those results, intended for comparison, are found to be in good agreement with previously published materials [6, 11]. However, the CF_4 scintillation light yield differs from the results of [7] by a factor 2. As mentioned by this study, the contaminants in the gas are of great importance on the number of photons emitted, which we also observed when comparing measurements from a different gas provider (not shown).

Coincidence resolving time

Fig. 7(a,c) show the correlation distribution between the number of phe in each PMT for N_2 and CF_4 respectively, at 1 atm pressure. The red dashed lines represent the selections used to make the time coincidence distributions in Fig. 7(b,d).

The CRT measured values are $\sigma = 1.4$ ns for N_2 and $\sigma = 0.34$ ns for CF_4 . Despite of a decay time for CF_4 two times slower than the one for N_2 , the CRT for the

FIG. 6: (top) Sum of the photoelectrons seen by the PMTs for N_2 . (bottom) Sum of the photoelectrons seen by the PMTs for each α energy selected by the IC and fitted by a Gaussian distribution for CF_4 .

CF_4 has been improved by a factor 4. This can be attributed to a higher emission yield of the scintillation process, considering that the CRT evaluation follows a $(N_{phe})^{-1/2}$ trend [25] when the photodetectors and the trigger thresholds were the same for both gases.

System simulations

The decay times and the scintillation emission yields given in section were used as input parameters for the simulation of the detection system.

The time coincidence distributions are compared to the experimental ones in Fig. 8. Considering the large approximations that were made, for instance in the conversion of the scintillation emission yields, the simulation of the PMTs electronic responses and the trigger system coupled with the Geant4 simulation allowed us to reproduce the coincidence resolving times for both gases with a correlation factor of 0.995 for both gases. Therefore, we estimated that further simulations of the system can be used using this procedure to evaluate the most appropriate conditions for the detection of heavier fission fragments.

CONCLUSION

Concerning the FALSTAFF project for the detection of fission fragments, the use of a scintillating ionisation

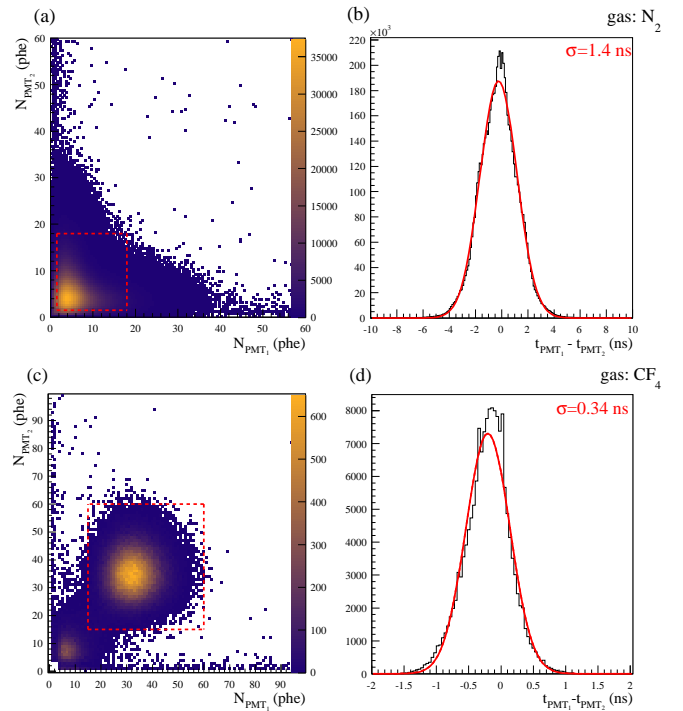

FIG. 7: (a) Correlation plot and (b) time coincidence distribution for N_2 , and (c), correlation plot and (d) coincidence time spectrum for CF_4 . The red dashed lines indicate the selections made for building the coincidence time spectra, the red solid lines represent the Gaussian fits applied to extract the coincidence time resolutions.

FIG. 8: Time coincidence distributions measured (solid black line) and simulated (blue strips filled) between the two PMTs in (a) N_2 and (b) CF_4 .

chamber could not achieve a better ToF resolution for the system than the CRT of the PMTs, even though it would be expected around 150 ps for higher deposited energies. The typical time resolution achieved by a Secondary Electron Detector primarily considered for this project, can in principle reach sigma values better than 130 ps and a 1.5 mm spatial resolution [26]. As a result, SEDs seem more suited than a scintillating ionization chamber to fulfill the requirements of this project.

However, the scintillating ionization chamber can be used as an active gaseous target for cross section measurements of interest for nuclear reactions induced by neutrons, envisioned at NFS [27]. This kind of experiment would require further studies on the scintillation properties of specific gaseous mixtures, completing some of the existing data [11, 28]. These studies are in progress and results are expected in a close future.
